A Chemical and Kinematic Analysis of HE2226−1529

Abigail Colclasure[1] and Maya Redden[1]

[1]*Department of Physics and Kavli Institute for Astrophysics and Space Research, Massachusetts Institute of Technology, Cambridge, MA 02139, USA*

ABSTRACT

We present a chemical and kinematic analysis of a bright, low mass, metal-poor star, HE2226−1529. Data were obtained using the MIKE spectrograph at Magellan Observatory. Additional astrometric data was obtained from Gaia and photometric measurements from the USNO catalog. Chemical analysis was performed using the SMHR and STARFIT softwares. Kinematic analysis was done using the ORIENT software which produces a kinematic history of the star. We find that HE2226−1529 has [Fe/H] = −2.79 and which designates it as a Population II, Very metal-poor (VMP) star. We classify it as an r-I process star that exists in the inner halo. The complete chemical and kinematic analysis of HE2226−1529 suggests that the star was formed from the gas of a neutron star merger and asymmetric supernova in a classical dwarf galaxy and was then accreted into the Milky Way early in its history.

1. INTRODUCTION

Metal-poor stars have a metallicity lower than one-tenth of the sun's metallicity, indicating an iron abundance ([Fe/H]) less than −2. They are classified as Population II stars which formed after the supernovae of the first stars of the universe which were metal-free and designated as Population III. Low-mass stars that formed in the early universe have changed little since their formation. Close examination of their spectra reveals information about the universe's chemical composition at the time of their formation (Becker et al. 2012). Past analyses of metal-poor stars have enabled the study of the first supernovae and their nucleosynthetic pathways (Umeda & Nomoto 2003). Other methods of observation of the early universe often require highly-advanced and expensive technologies that can detect objects far into the high redshift universe. Metal-poor stars in the Milky Way are the local equivalent of these objects.

HE2226−1529 has been identified as a metal-poor star by performing medium resolution spectroscopy on bright stars in the Hamburg/ESO survey (Frebel et al. 2006). This study confirms that finding and provides a possible nucleosynthesis interpretation and kinematic history. We summarize the observations made in section 2, analyze the stellar chemical abundance and provide stellar parameters in section 3, discuss the star's progenitor in section 4, and provide a kinematic analysis in section 5.

2. OBSERVATIONS AND MEASUREMENTS

This section provides a summary of how HE2226−1529 was observed and how basic measurements, namely the heliocentric radial velocity and the equivalent widths of the spectral features, were made.

2.1. *Telescope Observations*

Observations of HE2226−1529 were made on June 23, 2014 using the Magellan Inamori Kyocera Echelle (MIKE) spectrograph with slit size 0.70" x 5.00" at the Las Campanas Observatory in Chile. HE2226−1529 is located at R.A. = 22:29:17.31 and Dec = −15:13:53.55. The data have a signal-to-noise ratio per pixel of 151.3, 113.1, 154.4, and 131.1 at 5200 Å, 4800 Å, 6000 Å, and 6500 Å respectively. Several representative portions of the spectrum are shown in Figure 3.

2.2. *Radial Velocity Measurements*

The radial velocity of HE2226−1529 was determined using the cross-correlation method as described by Tonry & Davis (1979). The spectrum was compared to the spectrum of reference star HD140283, which is correctly calibrated to be at rest in the heliocentric frame. The measure of correlation for radial velocities in the range of −200 km/s to −100 km/s is shown in Figure 1. The adjusted spectrum from the cross-correlation method was plotted over the reference spectrum and
Figure 1: Cross-Correlation Result.

Figure 2: Radial Velocity Corrected Spectrum.

Standard Star	Temperature [K]	[Fe/H]
HD122563	4600	−2.7
HE1523−0901	4630	−3.0
CS22892−52	4800	−3.1
HD140283	5650	−2.5
G64−12	6450	−3.2
CD−38 245	4800	−4.1

Table 1: Standard Star Properties

are slightly stronger, the iron abundance is estimated to be around −3.0.

2.4. *Equivalent Width Measurements*

The equivalent widths of 430 emission lines were measured using the Spectroscopy Made Harder (SMHR) software (Casey 2014). SMHR fits a curve (either Gaussian, Voigt, or Lorentzian) to each dip at known transition wavelengths. The fit of each line was checked manually and adjusted if necessary. Irregular, highly noisy, or otherwise obviously sub-standard lines were discarded during this check. The area under these curves is taken to be linearly related to the abundance of the respective element and thus the abundances are calculated. The abundances found by the equivalent width method using SMHR are shown in Tables 5-9 in the appendix and discussed further in Section 3.7.

3. CHEMICAL ABUNDANCE ANALYSIS

A chemical analysis of HE2226−1529's spectrum is used to determine the stellar parameters including metallicity, effective temperature, surface gravity, and microturbulence.

3.1. *Stellar Parameter and Abundance Determination*

The stellar parameters that were found for the star include the metallicity, effective temperature, surface gravity, and microturbulence. The parameters are calculated in an iterative process as the metallicity measured from the spectrum is dependent on the other parameters and vice versa. Initial approximations for each parameter must be made and then continuously adjusted until a stable state is reached. The final stellar parameter values are accounted for when determining chemical abundances.

A 1D model atmosphere with alpha enhancement was used for the abundance determination. Further, we required that the Fe I and Fe II abundances were in agreement with each other. We also minimized the spread of abundances of each individual Fe line across excitation potential by inspection and adjustment of all extreme outliers. This was to ensure that all measured lines would agree with a single abundance value as expected.

manually adjusted to minimize the difference between the corrected HE2226−1529 spectrum and the reference spectrum. The radial velocity found from this method was then corrected to be in reference to the heliocentric frame. The final heliocentric radial velocity is calculated to be −138.4 km/s and the final corrected spectrum compared to that of a standard star is shown in Figure 2.

2.3. *Summary of Spectrum*

Visual inspection of the spectrum plotted over spectra of standard stars (Figure 3) gives rough estimates for two of HE2226−1529's characteristics. The properties of the standard stars are shown in Table 1, these stars have been well studied and these data come from the literature. In the H-beta region, there is a clear relationship between temperature and the rate of dropoff around the H-beta line. We use this relationship to estimate the temperature of HE2226−1529 around 5000K. In the Mg region, the spectrum of the star is shown over the spectrum of CS22892−52 which has an effective temperature of 4800K and [Fe/H] = −3.1. Given their similar temperatures and noting that the Mg lines of HE2226−1529
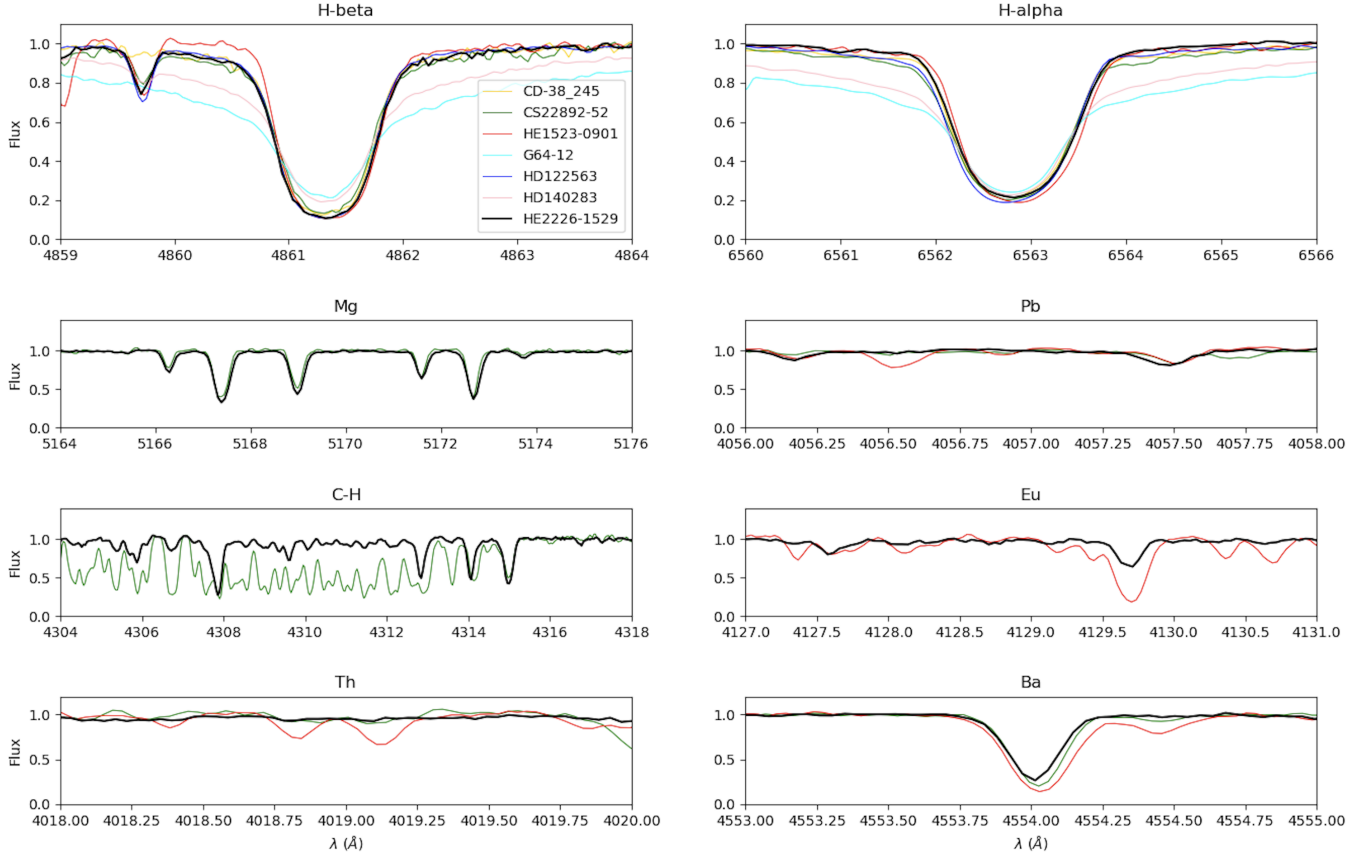

Figure 3: Spectrum Summary.

3.2. *Metallicity [Fe/H]*

Metallicity was determined from the measured equivalent widths in SMHR. [Fe/H] is measured to be −2.79 +/− 0.15. Therefore we categorize HE2226−1529 as a Population II, metal-poor star. The abundance of each measurable Fe line is shown in Figure 4. The trend is approximately flat as expected (the reader is asked to note the scale of the axes in Figure 4).

3.3. *Effective Temperature*

We calculate an effective temperature of 4915 K. The effective temperature of HE2226−1529 was determined using photometry. For these calculations, we used the photometric magnitudes given in the USNO catalog, shown in Table 2. The calculations followed the method outlined by Alonso, A. et al. (1999) and Casagrande et al. (2010).

3.4. *Surface Gravity*

The surface gravity is computed to be 1.55 +/− 0.06 dex using the parallax and fundamental equations. In order to calculate surface gravity, the bolometric correction must be computed first. It is the correction made
Figure 4: Abundances of Measured Iron Lines.

to the star's visible magnitude in order to obtain its absolute magnitude. Here, the bolometric correction is calculated using the method given by Alonso, A. et al. (1999) (eq. 18). We assume a stellar mass of 80 percent of the Sun's mass. This stellar mass is assumed because the star is likely to be 12-13 billion years old (due to its low metalicity) and because it is likely on the giant

Filter	Magnitude	Error
B	13	
V	12.248	0.01
g	12.656	
H	9.993	
J	10.426	0.023
K	9.923	0.025
E(B−V)	0.0341	0.0004

Table 2: Photometric Magnitudes of HE2226−1529

branch. Finally, the surface gravity is calculated using the following equation:

$$\log \frac{g}{g_{\odot}} = \log \frac{M}{M_{\odot}} + 4\log \frac{T_{eff}}{T_{eff,\odot}} + 0.4(M_{bol} - M_{bol,\odot}) \tag{1}$$

3.5. Microturbulence

We compute a microturbulence of 2.15 km/s. Microturbulence is a free factor that is used to account for strong line widening caused by turbulent motion in the photosphere. It provides a correction so that the same abundance is obtained from a given element, regardless of if the line detected is weak or strong. Therefore, microturbulence has a stronger effect on stronger lines and little to no effect on weak lines. Microturbulence values can be determined by minimizing the trend in abundances versus reduced equivalent widths. A relationship between microturbulence and surface gravity has been established using data from Hansen et al. (2018), Sakari et al. (2018), Ezzeddine et al. (2020), Holmbeck et al. (2020), and Barklem et al. (2005).

3.6. Chemical Abundance Results

Chemical abundances can be determined using the equivalent width of each spectral line and a curve of growth. Here, this is done with SMHR. All of the observed absorption lines are sufficiently weak (unsaturated) with a small optical depth such that they fall on the linear portion of the curve of growth. Thus, the abundance can be calculated in a straightforward fashion. The spectrum synthesis method was used for determining the abundances of C-H, Sr II, Ba II, Eu II, Y, and Zr by finding the best fit synthesized spectrum to match the hyperfine structure seen in these elements' absorption patterns.

3.6.1. Abundance Results

Abundances for 24 elements were measured. Table 3 shows the different elements and the number of measured lines for each element N. All but 2 elements had

Element	$\log \epsilon(X)$	[X/H]	[X/Fe]	stderr	N
C I	5.17	−3.26	−0.46	0.1	2
Na I	3.97	-2.27	0.52	0.07	2

Table 3: Chemical abundances of HE2226−1529.

fewer than 25 measured lines. Small sample statistics were accounted for as discussed in Section 3.9. The measured abundances of each element using the equivalent widths method is shown in Table 3. Elemental abundances of HE2226−1529 are found to be consistent with typical halo stars. In particular, this is indicated by the abundances of Cr, Mn, Co, and Ni (Hollek et al. 2011). Figure 5 provides a comparison of all measured elemental abundances to other metal-poor halo stars in the JINAbase.

3.6.2. Light Element Abundance Trends

All light element abundances fall within typical values, except for carbon. We find an unexpectedly low carbon abundance ([C/Fe]) of −0.46. This finding is peculiar because it is accompanied by a relatively high [Zn/Fe] ratio of 0.42. In a typical fallback supernova, it is expected that a high Zn abundance is accompanied by a high C abundance and a low Zn abundance is accompanied by a low C abundance. For comparison purposes, we look at the C and Zn abundances of halo stars from JINAbase with [Fe/H] greater than −3 and less than −2, as shown in Figure 6. We see HE2226−1529 as hav-
Figure 5: Abundance comparison of HE2226−1529 to other metal-poor stars from JINAbase. HE2226-1529 is identified by the blue star.

ing a lower [C/Zn] than most stars in this range. The implications of this are discussed in Section 4.

3.6.3. *Iron-peak Abundance Trends*

Like iron, the other iron-peak elements (Sc through Zn) were formed only by supernovae in the early universe. Given our low [Fe/H], we expect to see abundances for these elements that also match the predicted yield of one supernova. We see in Figure 5 that these

abundances do fall among other metal-poor stars, with the exception of vanadium. This is likely due to measurement error as only 2 measurable lines were used to calculate the vanadium abundance.

3.6.4. *Heavy Element Abundance Trends*

The Eu, Ba, and Sr abundances point to an r-process star. Main r-process stars are those with [Eu/Fe] between 0.3 and 1 and [Ba/Eu] less than 0 (Beers &

Figure 6: HE2226−1529 compared to stars in JIN-Abase with [Fe/H] > −3 and < −2 with respect to their C and Zn abundances. HE2226-1529 is identified by the red star.
Christlieb 2005). HE2226−1529 has [Eu/Fe] of 0.62 and [Ba/Eu] of −0.39, so it is classified as an r-I star. The implications of this classification are discussed further in Section 4.

3.7. *Abundance Uncertainties*

Random uncertainty in the abundance values arises from a number of sources including resolution limitations of the telescope and spectrograph, and choices made in the process of measuring the spectrum. Errors were given by the SMHR software based on the model fit for each absorption feature.

The standard errors of abundances measured from 25 or fewer lines were adjusted to reflect their small sample size. These adjustments were made by taking the product of the maximum difference of the abundance measurements for a given element and a factor corresponding to the number of lines as computed by small sample statistics. In addition, a minimum nominal uncertainty of 0.05 dex was applied to all elements. This minimum nominal uncertainty was determined using the Fe I lines.

We get systematic uncertainties of each abundance by varying the stellar parameters singly by their approximated statistical uncertainties and noting the change in abundance of each element. For all elements, the systematic uncertainty was found to be within three standard deviations of the error bars. This can be seen in Table 4.

4. NUCLEOSYNTHETIC INTERPRETATION OF STELLAR ABUNDANCES

The observed abundances of HE2226−1529 can be compared to model nucleosynthesis yields from the first

Element	Random Error	ΔT_{eff} $+ 100$ K	$\Delta \log g$ $+ 0.3$ dex	Δv_{micr} $+ 0.3\,\text{km}\,\text{s}^{-1}$

Eu II	0.2	0.07	0.09	−0.08

Table 4: Chemical Abundance Uncertainties

massive supernovae. This is done using the STARFIT tool from Monash University (Heger & Woosley 2010). STARFIT produces a model of supernova nucleosynthesis yields that most closely fits the stellar abundances. From this model and the true abundances, we gain insight into the enrichment history of the star's original nebula. This information includes the supernova explosion energy and the progenitor's mass.

We see in Figure 7 the observed element abundances do not closely fit the model produced by STARFIT. Most noticeably, we see a lower carbon abundance and a higher zinc abundance than would be predicted by the model. The most likely causes for these two differences are contradictory. The low carbon abundance suggests a low explosion energy of the gas-forming supernova and the high zinc abundance suggests a high explosion energy. We conclude that the progenitor event was not a typical fallback supernova. Possible explanations for the observed carbon and zinc abundances include an asymmetric supernova wherein the carbon was expelled at a higher velocity along a certain direction as opposed to evenly in all directions. Further analysis of this carbon and zinc signature is outside the scope of this paper.

As discussed in Section 3.6.4, europium and barium abundances of HE2226−1529 are indicative of an r-I star. The only currently accepted events wherein

Figure 8: Orbital history of HE2226−1529 produced by the ORIENT.

r-process nucleosynthesis can occur are neutron star merger (NSM) events, therefore we assume an NSM must have occurred to produce the r-process elements in the progenitor galaxy (Ji et al. (2016), Abbott et al. (2017a), and Abbott et al. (2017b)). This suggests an upper limit on the star's age as the NSM requires adequate time to take place.

5. KINEMATIC ANALYSIS

A kinematic analysis provides important information, in addition to a chemical analysis, about a star's origin. Here, we use astrometric data obtained from Gaia DR3, as well as radial velocity measurements. These data were obtained from the Gaia mission archive website. The distance from the Earth to HE2226−1529 was calculated using its parallax. Parallax is the apparent change in the position of the star due to the Earth's orbital motion. HE2226−1529 has a parallax of 0.2163" with an error of 0.0139". The distance of the star to the Earth can be simply obtained by inverting the parallax. We compute an uncorrected distance to HE2226−1529 of 4.6 kpc. Further, a pseudocolor is not available for this star so we used a fixed zero parallax correction instead. This calculation was done following the method outlined in Lindegren et al. (2021). HE2226−1529 has a corrected distance of 3.8 kpc. Unfortunately, reliable distances from Gaia cannot be computed so simply. Small uncertainties in parallax that result from the operations of the Gaia spacecraft itself can cause large uncertainties in distance calculated. Therefore, we do a probabilistic analysis following the work of Bailer-Jones et al. (2021). A probabilistic distance is calculated using a Monte Carlo simulation that assumes an exponentially decreasing space density prior. We conclude that HE2226−1529 is located 3.8 +/− 0.2 kpc away from Earth. Thus, this star is likely located in the halo.
5.1. *Orbital Motions*

The orbital history of HE2226−1529 can be described using the ORIENT (Mardini et al. 2020), an evolution model of the Milky Way. The model uses a cosmologically derived time-varying galactic potential and back integrates to create a simulation of the orbital history of the star given its current position and velocity in the galaxy. The potential is derived from a gas and dark matter sphere and stellar matter disk.

We compute a U velocity of −44.82 km/s, a V velocity of −174.02 km/s and a W velocity of 69.25 km/s. From the simulation, we see a clear picture of HE2226−1529 moving in the inner halo as seen in Figure 8. The large negative V velocity and small maximum Z height are indicators of this. This agrees with the chemical analysis which also placed the star in the halo with high probability.

The reader should note that the orbital history created by the ORIENT model does not produce estimates of accretion times and it is possible the star was accreted after the earliest time in the simulation, approximately 8 Gyr ago. To explain its existence in the inner halo, however, it is likely HE2226−1529 was accreted early in the history of the Milky Way. After being accreted, the star would have moved in the outer halo before being pulled into the inner halo where it exists today.

6. SUMMARY AND CONCLUSIONS

Here, we presented a chemical and kinematic analysis of a bright, low mass, metal-poor star, HE2226−1529. We gave a summary of observations made and the ways in which abundances and stellar parameters were determined. We compared the chemical abundances of HE2226−1529 to other low-mass stars and fit a model to our data. We conclude that HE2226−1529 is an r-

I process star, accreted into the inner halo, and formed from an asymmetric supernova. In the future, a more in-depth kinematic analysis of may be useful to date when HE2226−1529 was accreted by the Milky Way. We also propose to repeat the analysis with a 3D model atmosphere, instead of a 1D model atmosphere.
